Orai1 and STIM1 move to the immunological synapse and are up-regulated during T cell activation

*Department of Physiology and Biophysics and ‡Center for Immunology, University of California, Irvine, CA 92697; and †TorreyPines Therapeutics, Inc., La Jolla, CA 92037

For efficient development of an immune response, T lymphocytes require long-lasting calcium influx through calcium release-activated calcium (CRAC) channels and the formation of a stable immunological synapse (IS) with the antigen-presenting cell (APC). Recent RNAi screens have identified Stim and Orai in Drosophila cells, and their corresponding mammalian homologs STIM1 and Orai1 in T cells, as essential for CRAC channel activation. Here, we show that STIM1 and Orai1 are recruited to the immunological synapse between primary human T cells and autologous dendritic cells. Both STIM1 and Orai1 accumulated in the area of contact between either resting or super-antigen (SEB)-pretreated T cells and SEB-pulsed dendritic cells, where they were colocalized with T cell receptor (TCR) and costimulatory molecules. In addition, imaging of intracellular calcium signaling in T cells loaded with EGTA revealed significantly higher Ca2+ concentration near the interface, indicating Ca2+ influx localized at the T cell/dendritic cell contact area. Expression of a dominant-negative Orai1 mutant blocked T cell Ca2+ signaling but did not interfere with the initial accumulation of STIM1, Orai1, and CD3 in the contact zone. In activated T cell blasts, mRNA expression for endogenous STIM1 and all three human homologs of Orai was up-regulated, accompanied by a marked increase in Ca2+ influx through CRAC channels. These results imply a positive feedback loop in which an initial TCR signal favors up-regulation of STIM1 and Orai proteins that would augment Ca2+ signaling during subsequent antigen encounter.

Results

Orai1 and STIM1 Are Recruited to the Immunological Synapse. Using primary human T cells or Jurkat T cells cotransfected with GFP-Orai1 and STIM1, we tested whether Orai1 and STIM1 are recruited to the IS upon activation of T cells by contact with superantigen (SEB)-pulsed autologous dendritic cells. Under control conditions without the APC, Orai1 is distributed throughout the cell surface, consistent with plasma membrane localization, whereas the majority of STIM1 was found in an ER pattern of localization [Fig. 1A and supporting information (SI) Fig. 7A]. After treating cells with thapsigargin (Tg), a sarcoplasmic endoplasmic reticulum calcium ATPase (SERCA) inhibitor applied in calcium-free solution to deplete the intracellular Ca2+ store, STIM1 formed puncta and became partially colocalized with Orai1 at the cell surface (Fig. 1A Right). Thus, consistent with the findings in refs. 3, 8, and 11, both STIM1 and Orai1 puncta are found distributed along the entire plasma membrane in store-depleted cells. In contrast, after contact between a T cell and an antigen-pulsed dendritic cell, a pronounced polarization of both STIM1 and Orai1 can be seen (Fig. 1B). Notably, both overexpressed GFP-Orai1 and endogenous Orai1 (SI Fig. 7B) accumulated at high density within the contact zone, in addition to their remaining localization along the rest of the T cell surface. Dendritic cells also demonstrated endogenous Orai1 and low-level STIM1 immunostaining, although without detectable redistribution to the interface (shown for Orai1 in SI Fig. 7B). STIM1 in T cells redistributed more extensively to the T cell/APC interface, with only few puncta found in the contact-free zone. Similar patterns of staining were observed in both resting and SEB-activated T cells cocultured with autologous SEB-pulsed dendritic cells or with Raji B cells as APC (Fig. 1 and supporting information).
We further showed that Orai1 is colocalized with CD3 and costimulatory CD28 molecules known to be recruited to IS in T cell/APC conjugate pairs (Fig. 2A and B). Consistent with a multifocal synapse (16, 17), the Orai1 distribution overlapped with both CD3 and lymphocyte function-associated antigen-1 (LFA-1) (Fig. 2C). These results demonstrate that STIM1 and Orai1 are recruited to the IS within the T cell/APC zone of contact.

**Relocalization of Orai1 and STIM1 to the Interface Does Not Require Calcium Signaling.** Imaging of living cells confirmed Orai1 and STIM1 accumulation at the immunological synapse and allowed us to examine the kinetics of synaptic recruitment of Orai1 and STIM1. SEB-pretreated human T lymphocytes were cotransfected with GFP-Orai1 and YFP-STIM1 and imaged during migrating and interaction with autologous SEB-pulsed dendritic cells. Before contact with APC, Orai1 in the motile T cells was localized at the cell surface and in the uropod (posterior of the moving polarized lymphocyte), and STIM1 was mostly in the uropod. Contact of the T cell leading edge with an APC induced T cell rounding and establishment of a stable contact with the dendritic cell. Both Orai1 and STIM1 redistributed, accumulating at the T cell/APC interface (Fig. 3 and SI Movie 1) over a 5-min period, during which Ca\(^{2+}\) signaling (data not shown) was initiated.

We further tested whether synaptic recruitment of Orai1, STIM1, and TCR components requires calcium influx through CRAC channels. Point mutation of the conserved glutamate in the loop between S1 and S2 (E106 of human Orai1, E180 in Drosophila Orai) to an alanine or glutamine results in a nonconducting CRAC channel and inhibits native CRAC current, indicating a dominant-negative action that is likely mediated by heteromultimerization with native wild-type Orai or Orai1 subunits (6, 9, 10). Expression of a nonconducting dominant-negative mutant of Orai1 (E106A), identified by fluorescence from the GFP tag, blocked Ca\(^{2+}\) entry in Jurkat and primary human T cells (SI Fig. 9A) but did not disturb initial TCR.
show that Ca\(^{2+}\) influx, using exogenous Ca\(^{2+}\) is restricted to areas of STIM1/Orai1 puncta formation (11).

Lioudyno et al. demonstrated interface-associated clustering of mutant Orai1, STIM1, and CD3 after short (10 min) coinubation with SEB-pulsed Raji B lymphocytes (SI Fig. 9), consistent with a reduced electrochemical driving force for Ca\(^{2+}\) entry in T cells upon antigen presentation is enhanced at the IS where STIM1 and Orai1 accumulate. Before coincubation with SEB-pulsed dendritic cells, T lymphocytes were loaded with the Ca\(^{2+}\) indicator fluo-4 along with EGTA, a slow high-affinity Ca\(^{2+}\) buffering to localize the sites of Ca\(^{2+}\) influx in T cells making contact with APCs (20). Whole-cell recordings in activated human T cells confirmed functional CRAC channel activity, but not voltage-gated Ca\(^{2+}\) channel activity, under the same conditions that produced voltage-gated Ca\(^{2+}\) current in PC12 cells (SI Fig. 10A–D). Monitoring of the intracellular Ca\(^{2+}\) concentration ([Ca\(^{2+}\)]\(_i\)) during elevation of external potassium provides a sensitive assay for the type of Ca\(^{2+}\) channel. Again, voltage-gated Ca\(^{2+}\) channel activity was revealed in PC12 cells but not in resting or activated human T cells (SI Fig. 10E and F). Instead, Tg-dependent Ca\(^{2+}\) influx in T cells was inhibited by high external potassium in a concentration-dependent manner (SI Fig. 10G), consistent with a reduced electrochemical driving force for Ca\(^{2+}\) entry through the CRAC channel. We conclude, therefore, that Ca\(^{2+}\) influx, specifically through CRAC channels, is significantly potentiated after TCR engagement.

Orai1, -2, and -3 and STIM1 mRNA Expression Is Up-Regulated in Activated T Cells. Studies have shown that STIM1 and Orai1 are essential for Ca\(^{2+}\) signaling in T cell lines (4, 5, 22). We

Local Calcium Influx at the T Cell/Dendritic Cell Interface. After calcium store depletion by thapsigargin, CRAC channel activity is restricted to areas of STIM1/Orai1 puncta formation (11). Using exogenous Ca\(^{2+}\) buffering to localize the sites of Ca\(^{2+}\) entry in T cells, we tested whether Ca\(^{2+}\) influx induced in T cells upon antigen presentation is enhanced at the IS where STIM1 and Orai1 accumulate. Before coincubation with SEB-pulsed dendritic cells, T lymphocytes were loaded with the Ca\(^{2+}\) indicator fluo-4 along with EGTA, a slow high-affinity Ca\(^{2+}\) buffer. Under these conditions, Ca\(^{2+}\) entering the cell would bind rapidly to the dye, producing a fluorescent signal, and then be captured by EGTA. In the presence of 2 mM extracellular Ca\(^{2+}\), many of those T cells that formed tight contacts with dendritic cells generated Ca\(^{2+}\) oscillations typical for T cells interacting with APCs (Fig. 4A and B). In addition, an apparent gradient of intracellular Ca\(^{2+}\) with a significantly higher concentration near T cell/dendritic cell interface was observed (Fig. 4A), suggesting that CRAC channels clustered near the interface mediate localized Ca\(^{2+}\) influx in T cells upon contact with APCs. Upon removal of external Ca\(^{2+}\), Ca\(^{2+}\) fell to the same level on both proximal and distal sides of the cell. Subsequent readuction of external Ca\(^{2+}\) reestablished the gradient across the cell, revealing significantly higher Ca\(^{2+}\) influx near the interface compared with other parts of the cell, occurring as soon as 1 s after readduction of Ca\(^{2+}\) (proximal versus distal areas, Fig. 4C). The rate of Ca\(^{2+}\) rise was also significantly higher near the interface compared with the more distal part of the T cell. Furthermore, in similar experiments performed by using ratio-metric Ca\(^{2+}\) measurement in Jurkat T cells loaded with fura-2 together with increased EGTA, the Ca\(^{2+}\) level near the interface with APC (proximal) was higher compared with that seen more distally after formation of stable contacts with antigen-presenting Raji B cells (Fig. 4D). Such a difference was never observed in the absence of exogenous intracellular buffering by EGTA (data not shown). Because exogenous Ca\(^{2+}\) chelation was required to reveal the gradients, it is unlikely that the gradients were due to dye compartmentalization. These results show that Ca\(^{2+}\) influx in T cells making contact with APCs preferentially occurs at the interface where STIM1 and Orai1 accumulate.

CRAC Channel-Mediated Ca\(^{2+}\) Influx Is Increased in Activated Human T Lymphocytes. During a second encounter with antigen/APC, TCR engagement induces a stronger Ca\(^{2+}\) signal and a more rapid and profoundly enhanced immune response, compared with that of naive T cells (18, 19). To activate primary human T cells fully in vitro, we incubated them with plate-bound anti-CD3 in combination with costimulatory anti-CD28 antibody. Under these conditions, T cells up-regulated CD69 expression and proliferated robustly (data not shown). Application of anti-CD3 and -CD28 antibodies consistently induced stronger Ca\(^{2+}\) signaling and higher rates of Ca\(^{2+}\) influx in previously activated T cells compared with resting T cells (Fig. 5). The level of CRAC channel activity evoked by store depletion with Tg was also significantly greater in activated T cells, assessed both by the sustained Ca\(^{2+}\) signal (2.7-fold increase, compared with resting cells) and the maximal rate of Ca\(^{2+}\) rise (dCa\(^{2+}\)/dt, 4.7-fold increase; Fig. 5 C and E), consistent with the results in ref. 20. These changes were observed by the second day of activation and lasted for at least 6 days (Fig. 5D). We found no evidence for involvement of voltage-gated Ca\(^{2+}\) channels in either resting or activated human T lymphocytes, in contrast to suggestions that voltage-gated Ca\(^{2+}\) channels mediate or participate in TCR-induced Ca\(^{2+}\) signaling (21). Whole-cell recordings in activated human T cells confirmed functional CRAC channel activity, but not voltage-gated Ca\(^{2+}\) channel activity, under the same conditions that produced voltage-gated Ca\(^{2+}\) current in PC12 cells (SI Fig. 10A–D). Monitoring of the intracellular Ca\(^{2+}\) concentration ([Ca\(^{2+}\)]\(_i\)) during elevation of external potassium provides a sensitive assay for the type of Ca\(^{2+}\) channel. Again, voltage-gated Ca\(^{2+}\) channel activity was revealed in PC12 cells but not in resting or activated human T cells (SI Fig. 10E and F). Instead, Tg-dependent Ca\(^{2+}\) influx in T cells was inhibited by high external potassium in a concentration-dependent manner (SI Fig. 10G), consistent with a reduced electrochemical driving force for Ca\(^{2+}\) entry through the CRAC channel. We conclude, therefore, that Ca\(^{2+}\) influx, specifically through CRAC channels, is significantly potentiated after TCR engagement.
confirmed the central role of Orai1 and STIM1 in resting primary T cells; knocking down STIM1 or Orai1 separately with RNAi significantly reduced Ca\textsuperscript{2+} influx, assessed by Tg-evoked peak Ca\textsuperscript{2+} levels (data not shown) and the rate of Ca\textsuperscript{2+} rise, dCa\textsuperscript{2+}/dt (SI Fig. 11A). Global changes in gene expression are characteristic of T cell activation (23). As shown in Fig. 6A and B, mRNA expression of STIM1 and all three Orai homologs was significantly increased in activated T cells, compared with resting cells. As expected, the expression of IL-2R\textalpha mRNA was also consistently up-regulated in activated cells, serving as a positive control (24), whereas mRNA expression for a housekeeping ribosomal gene, Rig/S15, was not changed. The three Orai homologs, expressed as homomultimers, exhibit distinct pharmacological sensitivity to 2APB (25). Tg-evoked Ca\textsuperscript{2+} influx in both resting and activated T cells is potentiayed by a low concentration (5 $\mu$M) of 2APB, and inhibited by a higher 2APB concentration (50 $\mu$M) (SI Fig. 11B), consistent with effects of 2APB on Orai1-induced CRAC current, but not channels formed by expression of Orai3 (25). Because Orai1 is a major contributor to store-operated calcium influx in human T lymphocytes, in contrast to Orai2, which has little role (22), or Orai3, which has distinct pharmacological properties (25), we conclude that up-regulation of Orai1 and STIM1 most likely contributes to the enhanced store-operated Ca\textsuperscript{2+} influx in activated T cells (Fig. 5), although potential contributions of heteromultimers need to be evaluated further.

**Discussion**

Our study demonstrates that Orai1 and STIM1—the CRAC channel pore subunit and its activator, respectively—are rapidly recruited to the region of contact between human T lymphocytes and autologous antigen-presenting dendritic cells, resulting in enhanced localized calcium influx in the T cell at the T cell/APC interface. It was shown in solitary T cells that the location of active CRAC channels after store depletion induced by thapsigargin treatment is closely associated with STIM1 puncta in the ER and with colocalized Orai1 in the plasma membrane (11). We also found puncta of colocalized STIM1 and GFP–Orai1 scattered throughout the entire periphery of T cells treated with thapsigargin. Here, we extend these results to the physiological context of human T cells interacting with an antigen-presenting dendritic cell and show that Orai1 and STIM1 colocalize with CD3, CD28 and LFA-1, demonstrating that both Orai1 and STIM1 are recruited to the IS. T cell Ca\textsuperscript{2+} influx is higher in this region than at the distal pole of the cell, as revealed by [Ca\textsuperscript{2+}]; gradients when Ca\textsuperscript{2+}
buffering was augmented exogenously by EGTA, a slow Ca^{2+} chelator. These findings are consistent with accumulation of functional CRAC channel components promoting localized Ca^{2+} influx at the IS.

Before establishment of a stable contact with APC, we found STIM1 predominantly in the trailing uropod, indicating ER localization at the rear of the motile T cell. In a previous study of cytotoxic T cells interacting with their targets in the absence of exogenous buffering, the earliest Ca^{2+} response was observed at the distal pole of the cell, creating a transient gradient of [Ca^{2+}], that was highest at the rear end of the cell immediately after contact formation (26). This early Ca^{2+} gradient may have resulted from IP_{3}-induced Ca^{2+} release initially at the trailing edge of the cell, leading to STIM1 puncta formation and initiation of CRAC channel activity. Within a few seconds, the global Ca^{2+} signal was uniform. In our study, we show that CRAC channel components relocalize to and promote Ca^{2+} entry preferentially at the zone of contact with APC; these results are not in disagreement with the earliest Ca^{2+} signal occurring at the trailing edge of the cell where STIM1 is initially located. As a consequence of STIM1 relocalization and concentration of Orai1 in the IS, [Ca^{2+}] may be locally elevated immediately adjacent to the membrane in the IS. However, localized Ca^{2+} entry produces a uniform global Ca^{2+} signal in the absence of exogenous Ca^{2+} buffering.

Similar changes in the relocalization of CRAC channels and potassium channels take place during the first minutes of T cell activation. The two types of T lymphocyte potassium channel, Kv1.3 and KCa3.1, that are indirectly involved in functional Ca^{2+} signaling by regulating the membrane potential (27) are also recruited to the IS (28–30). Channel function and Ca^{2+} signaling does not appear important for initial IS formation, because inhibiting either K^{+} channel with channel blockers (29, 30) or CRAC channel function by expression of the nonconducting dominant-negative Orai1 subunit of the CRAC channel (SI Fig. 9) did not prevent molecular clustering in the contact zone. However, the long-term stability of the IS was shown to be compromised by blocking Ca^{2+} entry in combination with increasing intracellular Ca^{2+} buffering (31, 32), although the initial contact formation and redistribution of CD3 to the contact area was not affected (31). Thus, it is possible that the recruitment of potassium and CRAC channels to the IS where receptors, adhesion molecules, and costimulatory molecules also accumulate is important for long-term calcium-dependent regulation of the signaling events triggered upon antigen presentation.

In human T cells after activation, the magnitude of store-operated Ca^{2+} entry increases ~10-fold (20); the number of functional voltage-gated K^{+} channels made up of Kv1.3 subunits increases 3- to 4-fold (33); and the number of functional Ca^{2+}-activated K^{+} channels made up of KCa3.1 subunits increases 25-fold (34). Thus, all three channel types that are involved directly or indirectly in Ca^{2+} signaling in T cells are up-regulated upon mitogenic activation after TCR engagement. Our experiments revealed increased expression of Orai1 and STIM1 mRNA in activated T lymphocytes that may contribute to enhanced signaling in activated T cells. Coordinated up-regulation and colocalization of CRAC components (Orai pore subunit and activator STIM1) and KCa3.1 channels to the IS may provide positive feedback involving localized Ca^{2+} entry activating KCa3.1 that would enhance Ca^{2+} signaling in activated cells. In addition, we found up-regulation of endogenous Orai2 and Orai3 in activated human T cells. Although the stoichiometry of interaction of the CRAC channel and the exact mechanism of its activation are still unknown, both Orai2 and STIM1 are undoubtedly crucial for CRAC channel function in human T cells (4, 5, 22, 35). Recent findings (25, 35) suggest that Orai2 and Orai3 can form homomultimeric channel complexes with distinct pharmacological properties and Ca^{2+} sensitivity. The pharmacological sensitivity to 2-APB of Tg-evoked Ca^{2+} signaling in activated T cell parallels that of overexpressed Orai1, but not Orai2 or Orai3, in heterologous cells. However, because Orai1–3 can also heteromultimerize, it remains to be seen what role Orai2 and Orai3 or their heteromultimers play in the regulation of T lymphocyte function. Moreover, T cell proliferation is suppressed in T cells from SCID patients lacking functional CRAC channels due to mutation within the first transmembrane domain of Orai1 (5). One of the implications of Orai1 and STIM1 up-regulation in the early stages of an immune response would be to amplify and ensure CRAC channel-mediated Ca^{2+} signaling crucial for clonal expansion, differentiation and calcium-dependent regulation of gene expression in T cells. Thus, we propose that positive feedback between Ca^{2+} signal and expression of Orai1 and STIM1 would ensure increased response strength to subsequent encounters with antigen.

**Materials and Methods**

Jurkat or primary human T cells (resting or previously activated) were incubated together with SEB-pulsed Raji or autologous dendritic cells as APCs on poly-l-lysine-coated dishes, fixed, and stained for localization of STIM1, Orai1, CD3, CD28, and LFA-1, using antibody staining as described in *SI Materials and Methods*. For live-cell imaging, SEB-pulsed human T cells were cotransfected with GFP-Orai1 (*SI Materials and Methods*) and YFP-STIM1 (kindly provided by T. Meyer [Stanford University Medical Center, Stanford, CA]) and, 24 h later, added to autologous SEB-pulsed dendritic cells attached to poly-l-lysine-coated glass coverslips. Simultaneous monitoring of GFP- and YFP-positive T cell images were acquired by using an inverted Olympus IX81 microscope equipped with a Olympus PlanApo N 60 × 1.45 N.A. oil objective, a Roper Scientific (Photometrics) Cascade 650 CCD camera, and a T.I.L.L. Photonics Polychrome IV monochromator tuned to independently excite GFP (455 nm), YFP (525 nm), or fura-2 (355 nm and 385 nm). Temperature was maintained at 35–37°C during the entire period of imaging. Ca^{2+} imaging experiments, using fluo-4 or fura-2, were performed as described in ref. 4. Ca^{2+} buffering capacity was increased in T cells loaded with fluo-4/AM (4 μM, 30 min) and EGTA/AM (1 mM, 30 min) or fura-2/AM (2 μM, 30 min) and EGTA/AM (10 μM, 30 min) at room temperature, and images of T cells in T cells with APC were acquired under control of Metamorph software. Digital images were acquired for each wavelength, using Metamorph software. Whole-cell recording was performed at room temperature, using an EPC9 amplifier (HEKA Electronic). Intracellular solutions contained 5–10 mM MgCl_{2} to inhibit the endogenous MIC currents, as described in ref. 36. All solutions are described in *SI Table 1*.

The remaining methods on cells, transfection, constructs, RNAi, RNA isolation, and RT-PCR can be found in *SI Materials and Methods* and *SI Table 1*.
